Abstract—The objective of this paper is to investigate the use of observers in the sensorless control of induction motor drives. First, three recently proposed rotor flux and speed observers for induction motors are analyzed and compared using a unified notation. Unresolved issues for each method are noted. Then, an alternative rotor flux and speed observer architecture is described, which is simulated and tested experimentally. The conclusion of our study is that observers can perform well estimating the rotor speed and the estimates can be used in a control strategy instead of speed values obtained by the sensors.

I. INTRODUCTION

An observer is an auxiliary dynamical system that uses the plant’s input and output signals to generate an estimate of the plant’s state, which can then be employed to close the control loop. An observer can also be used to augment or replace sensors in a control system. Effective control strategies of induction motor drive systems require speed as well as the flux estimates. In this paper, we analyze and compare four different rotor flux and speed observers for induction motors using a unified notation. We first review the three recently proposed rotor flux and speed observers for induction motors and then describe an alternative rotor flux and speed observer architecture for an induction motor. We first analyze the adaptive flux observer of Kubota, Matsuse and Nakano [1], where Luenberger’s full-order observer is utilized to estimate the stator currents and rotor fluxes using the fourth-order portion of the fifth-order induction motor model in the stationary reference frame and assuming constant rotor speed. Then, a proportional-plus-integral formula is employed to implement the proposed scheme for speed estimation. The above architecture was also analyzed and tested in [2]. Next, we analyze the architecture of Derdiyok et al. [3], where the output of a sliding-mode observer is used in the formula for the flux to obtain an estimate of the rotor flux. We then compare the above two architectures with the rotor flux and speed sliding mode observer proposed by Utkin, Guldner and Shi [4], which is also based on the fourth-order portion of the fifth-order induction motor model in the stationary reference frame and assuming the constant rotor speed. We do not discuss in this paper the Vergheese and Sanders’ flux observer [5] where the authors focus on estimating the rotor flux only. For further discussion concerning the role the observers play in sensorless control of induction motors the reader may consult [6]. We then proceed with the development of an alternative observer for rotor flux and speed. We represent the standard model of the induction motor in the form

\[
\dot{x} = Ax + B_{1}u_{1} + B_{2}u_{2}(x, \tau_{L}),
\]

where the vector function \( u_{2} \) models lumped nonlinearities in the model and \( \tau_{l} \) is the load torque. The dynamics of the proposed observer are described by

\[
\dot{\hat{x}} = A\hat{x} + B_{1}\hat{u}_{1} + B_{2}u_{2}(\hat{x}, \hat{\tau}_{L}),
\]

where \( \hat{x} \) is the state estimate and \( \hat{\tau}_{L} \) is the load torque estimate.

II. INDUCTION MOTOR MODELING

A three-pole three-phase smooth air gap induction machine is shown in Figure 1. We use an equivalent two-phase two-pole representation shown in Figure 2. Definitions of state and control variables are given in Table I. Parameters that appear in the modeling equations are given in Table II. We first write the voltage equations for the 2-phase symmetrical smooth air-gap
cage induction motor model:

\[ u_{as} = R_s i_{as} + \frac{d\psi_{as}}{dt} = R_s i_{as} + L_s \frac{di_{as}}{dt} + L_m \frac{di_{ar}}{dt} \]

\[ u_{bs} = R_s i_{bs} + \frac{d\psi_{bs}}{dt} = R_s i_{bs} + L_s \frac{di_{bs}}{dt} + L_m \frac{di_{ar}}{dt} \]

\[ 0 = R_r i_{ar} + \frac{d\psi_{ar}}{dt} + L_r \frac{di_{ar}}{dt} \]

\[ 0 = R_r i_{br} + \frac{d\psi_{br}}{dt} + L_r \frac{di_{ar}}{dt} + L_m \frac{di_{ar}}{dt} \]

We assume that the magnetic system is linear and therefore the flux linkages may be expressed as linear functions of inductances and currents. The stator and rotor windings are in relative motion. When the magnetic axes are aligned, the magnetic coupling between the corresponding windings is maximized and the corresponding mutual inductance is positive and maximized. When the magnetic axes are perpendicular, the magnetic coupling is zero and the mutual inductance value is zero. Taking the above into account, we obtain

\[ u_{as} = R_s i_{as} + \frac{d\psi_{as}}{dt} = R_s i_{as} + L_s \frac{di_{as}}{dt} + L_m \frac{di_{ar}}{dt} \]

\[ u_{bs} = R_s i_{bs} + \frac{d\psi_{bs}}{dt} = R_s i_{bs} + L_s \frac{di_{bs}}{dt} + L_m \frac{di_{ar}}{dt} \]

\[ 0 = R_r i_{ar} + \frac{d\psi_{ar}}{dt} + L_r \frac{di_{ar}}{dt} \]

\[ 0 = R_r i_{br} + \frac{d\psi_{br}}{dt} + L_r \frac{di_{ar}}{dt} + L_m \frac{di_{ar}}{dt} \]

We next apply a model simplifying transformation of the 2-phase equivalent model. Specifically, we use the equivalent set of rotor flux linkages

\[ \begin{bmatrix} \lambda_{ar} \\ \lambda_{br} \end{bmatrix} = \begin{bmatrix} \cos(n_p \theta) & -\sin(n_p \theta) \\ \sin(n_p \theta) & \cos(n_p \theta) \end{bmatrix} \begin{bmatrix} \psi_{ar} \\ \psi_{br} \end{bmatrix} \]

to obtain

\[ \lambda_{ar} = L_r (i_{ar} \cos(n_p \theta) - i_{br} \sin(n_p \theta)) + L_m i_{as} \]

\[ \lambda_{br} = L_r (i_{ar} \sin(n_p \theta) + i_{br} \cos(n_p \theta)) + L_m i_{bs} \]

After some manipulations, we can represent the two-phase equivalent model of a three-phase cage induction motor in the form:

\[ \begin{bmatrix} \frac{d\omega}{dt} \\ \frac{d\lambda_{ar}}{dt} \\ \frac{d\lambda_{br}}{dt} \\ \frac{d\lambda_{as}}{dt} \\ \frac{d\lambda_{bs}}{dt} \end{bmatrix} = \begin{bmatrix} -\eta \lambda_{ar} - n_p \omega \lambda_{br} + \eta L_m i_{as} \\ -\eta \lambda_{br} + n_p \omega \lambda_{ar} + \eta L_m i_{bs} \\ \eta \beta \lambda_{ar} + n_p \beta \omega \lambda_{br} - \gamma i_{as} + \frac{1}{\sigma L_r} u_{as} \\ \eta \beta \lambda_{br} - n_p \beta \omega \lambda_{ar} - \gamma i_{bs} + \frac{1}{\sigma L_r} u_{bs} \end{bmatrix} \]

The above is the cage induction motor model in the stationary reference frame. We illustrate the above modeling equations in Figure 3.

### III. Kubota, Matsuse and Nakano’s Adaptive Flux and Speed Observer

Kubota, Matsuse and Nakano [1] use the following fourth-order portion of model (1) when constructing their observer,

\[ \begin{bmatrix} \frac{d\lambda_{ar}}{dt} \\ \frac{d\lambda_{br}}{dt} \\ \frac{d\lambda_{as}}{dt} \\ \frac{d\lambda_{bs}}{dt} \end{bmatrix} = \begin{bmatrix} -\eta \lambda_{ar} - n_p \omega \lambda_{br} + \eta L_m i_{as} \\ -n_p \omega \lambda_{br} - \gamma i_{as} + \frac{1}{\sigma L_r} u_{as} \\ \eta \beta \lambda_{ar} + n_p \beta \omega \lambda_{br} - \gamma i_{as} + \frac{1}{\sigma L_r} u_{as} \\ -n_p \beta \omega \lambda_{ar} - \gamma i_{bs} + \frac{1}{\sigma L_r} u_{bs} \end{bmatrix} \]
Kubota et al. [1] next postulate selecting \( L_r \) so that
\[
(A_r - L_r C_r)^T + (A_r - L_r C_r) < 0,
\]
which amounts to finding an observer gain matrix \( L_r \) so that
\[
V(e) = e^T e
\]
is a Lyapunov function for the system \( e = (A_r - L_r C_r) e \), that is,
\[
(A_r - L_r C_r)^T + (A_r - L_r C_r) = -Q,
\]
where \( Q = Q^T > 0 \). The above requirement greatly simplifies further analysis; however, sufficiency conditions for the existence of the gain matrix \( L_r \) such that (3) is satisfied is not discussed in their paper and appears to be unknown in the literature. Kubota et al. [1] then consider an augmented Lyapunov’s function candidate:
\[
V(e, \Delta \omega) = e^T e + \frac{1}{\alpha} (\hat{\omega} - \omega)^2,
\]
where \( \alpha > 0 \) is a design parameter. Recall that \( \Delta \omega = \hat{\omega} - \omega \). In their further development Kubota et al. [1] assume that \( \omega \) is constant. Then, evaluating the time derivative of \( V(e, \Delta \omega) \) on the trajectories of (2) gives
\[
\frac{d}{dt} V(e, \Delta \omega) = \frac{d}{dt} \left( e^T e + \frac{1}{\alpha} (\Delta \omega)^2 \right)
\]
\[
= 2e^T \dot{e} + \frac{2}{\alpha} \Delta \omega \frac{d}{dt} \Delta \omega
\]
\[
= 2e^T ((A_r - L_r C_r) e - \Delta A_r \dot{x})
\]
\[
+ \frac{2}{\alpha} \Delta \omega \frac{d}{dt} \Delta \omega
\]
\[
= -e^T Q e - 2e^T \Delta A_r \dot{x}
\]
\[
+ \frac{2}{\alpha} \Delta \omega \frac{d}{dt} \Delta \omega.
\] (4)

To proceed, we need to evaluate
\[
e^T \Delta A_r \dot{x}
\]
\[
= \begin{bmatrix}
\lambda_{ar} - \hat{\lambda}_{ar} & \lambda_{br} - \hat{\lambda}_{br} & i_{as} - \hat{i}_{as} & i_{bs} - \hat{i}_{bs}
\end{bmatrix}
\times
\begin{bmatrix}
0 & 0 & 0 & 0
\end{bmatrix}
\times
\begin{bmatrix}
\dot{\lambda}_{ar}
\dot{\lambda}_{br}
\dot{i}_{as}
\dot{i}_{bs}
\end{bmatrix}
\]
\[
= \Delta \omega \left( -\left( \lambda_{ar} - \hat{\lambda}_{ar} \right) n_p \hat{\lambda}_{br} + \left( \lambda_{br} - \hat{\lambda}_{br} \right) n_p \hat{\lambda}_{ar} + (i_{as} - \hat{i}_{as}) n_p \beta \hat{\lambda}_{br}ight.
\]
\[
\left. - (i_{bs} - \hat{i}_{bs}) n_p \beta \hat{\lambda}_{ar} \right)
\]
\[
= \Delta \omega \left( -\lambda_{ar} n_p \hat{\lambda}_{br} + \lambda_{br} n_p \hat{\lambda}_{ar} + (i_{as} - \hat{i}_{as}) n_p \beta \hat{\lambda}_{br}ight.
\]
\[
\left. - (i_{bs} - \hat{i}_{bs}) n_p \beta \hat{\lambda}_{ar} \right).
\]
Kubota et al. [1] assume, without stating this explicitly, that
\[ \lambda_{ar} n_p \hat{\lambda}_{br} = \lambda_{br} n_p \hat{\lambda}_{ar}, \]
that is,
\[ \lambda_{ar} \dot{\hat{\lambda}}_{br} = \hat{\lambda}_{ar} \lambda_{br}. \]  
(5)

Taking the above into account in the expression for \( e^T \Delta A_r \hat{x} \) yields
\[ e^T \Delta A_r \hat{x} = \Delta \omega (i_{as} - \hat{i}_{as}) n_p \beta \hat{\lambda}_{br} - (i_{bs} - \hat{i}_{bs}) n_p \beta \hat{\lambda}_{ar}. \]

Substituting the above into (4) gives
\[
\frac{d}{dt} V(e, \Delta \omega) = -e^T Q e + 2 \Delta \omega \left((i_{as} - \hat{i}_{as}) n_p \beta \hat{\lambda}_{br} - (i_{bs} - \hat{i}_{bs}) n_p \beta \hat{\lambda}_{ar}\right),
\]
then \( \frac{d}{dt} V(e, \Delta \omega) = -e^T Q e \leq 0 \) in the augmented \( \left[ \frac{e}{\Delta \omega} \right] \) space. Recall that the adaptive scheme was obtained under the assumption that \( \omega \) is constant. Kubota et al. [1] propose to use the PI control to implement the above scheme,
\[ \dot{\omega} = K_p \left((i_{as} - \hat{i}_{as}) n_p \beta \hat{\lambda}_{br} - (i_{bs} - \hat{i}_{bs}) n_p \beta \hat{\lambda}_{ar}\right) + K_I \int \left((i_{as} - \hat{i}_{as}) n_p \beta \hat{\lambda}_{br} - (i_{bs} - \hat{i}_{bs}) n_p \beta \hat{\lambda}_{ar}\right) dt. \]

In summary, the observer of Kubota, Matsuse, and Nakano [1] has the form,
\[
\frac{d}{dt} \begin{bmatrix} \hat{\lambda}_{ar} \\ \hat{\lambda}_{br} \\ i_{as} \\ i_{bs} \end{bmatrix} = \begin{bmatrix} -\eta & -n_p \hat{\omega} & \eta L_m & 0 \\ 0 & 0 & \eta L_m & 0 \\ -n_p \beta \hat{\lambda}_{br} & -\eta \beta & 0 & 0 \\ -n_p \beta \hat{\lambda}_{ar} & 0 & -\eta \beta & 0 \end{bmatrix} \begin{bmatrix} \hat{\lambda}_{ar} \\ \hat{\lambda}_{br} \\ i_{as} \\ i_{bs} \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ \frac{\sigma L_s}{i_{as}} \\ 0 \end{bmatrix} \begin{bmatrix} u_{as} \\ u_{bs} \end{bmatrix} + L_r \left( \begin{bmatrix} i_{as} - \hat{i}_{as} \\ i_{bs} - \hat{i}_{bs} \end{bmatrix} \right).
\]
\[ \dot{\omega} = K_p \left((i_{as} - \hat{i}_{as}) n_p \beta \hat{\lambda}_{br} - (i_{bs} - \hat{i}_{bs}) n_p \beta \hat{\lambda}_{ar}\right) + K_I \int \left((i_{as} - \hat{i}_{as}) n_p \beta \hat{\lambda}_{br} - (i_{bs} - \hat{i}_{bs}) n_p \beta \hat{\lambda}_{ar}\right) dt. \]

IV. SLIDING MODE OBSERVER OF DERDIYOK, GÜVEN, REHMAN, INANC AND XU

As in the observer of Kubota et al., Derdiyok et al. [3] use the fourth-order portion of the fifth-order induction motor model in the stationary reference frame. We now describe the representation of the model that Derdiyok et al. [3] use when constructing their observer. Let
\[ A_\omega = \begin{bmatrix} \eta & n_p \hat{\omega} \\ -n_p \omega & \eta \end{bmatrix}. \]

Then we can represent the reduced-order model as:
\[ \begin{align*}
\frac{d\lambda_r}{dt} &= -A_\omega \lambda_r + \eta L_m i_s \\
\frac{di_s}{dt} &= \beta A_\omega \lambda_r - \gamma i_s + \frac{1}{\sigma L_s} u_s.
\end{align*} \]

The following switching surface is defined,
\[ s = \begin{bmatrix} s_a \\ s_b \end{bmatrix} = \begin{bmatrix} i_{as} - i_{as} \\ i_{bs} - i_{bs} \end{bmatrix} = 0. \]

Let
\[ \nu = -v_0 \begin{bmatrix} \text{sign}(s_a) \\ \text{sign}(s_b) \end{bmatrix} = -v_0 \begin{bmatrix} \text{sign}(i_{as} - i_{as}) \\ \text{sign}(i_{bs} - i_{bs}) \end{bmatrix}. \]

Derdiyok et al. [3] propose the current observer:
\[ \frac{di_s}{dt} = \beta \nu - \gamma i_s + \frac{1}{\sigma L_s} u_s. \]

We now use the arguments of Derdiyok et al. [3] to show that the surface \( \{s = 0\} \) is attractive for sufficiently large gain \( v_0 \). For this we consider a generalized Lyapunov function candidate, \( V = 0.5 s^T s \), which can be viewed as a distance measure from \( \{s = 0\} \). We then find the Lyapunov derivative of \( V \), that is, the time derivative of \( V \) evaluated on the trajectories of the observer, \( \dot{V} = s^T \dot{s} \), where
\[ s = \frac{dx}{ds} - \frac{dx}{ds} = \beta (\nu - \beta A_\omega \lambda_r) - \gamma (i_s - i_s). \]

Let
\[ \text{sign}(x) = [\text{sign}(x_1) \; \text{sign}(x_2) \; \cdots \; \text{sign}(x_n)]^T. \]

Then
\[ \dot{V} = \beta (\dot{i}_s - \dot{i}_s)^T (\nu - \beta A_\omega \lambda_r) - \gamma \left\| \dot{i}_s - \dot{i}_s \right\|^2 = -\beta v_0 (i_s - i_s)^T \text{sign}(i_s - i_s) - \gamma \left\| \dot{i}_s - \dot{i}_s \right\|^2 + \beta^2 (\dot{i}_s - \dot{i}_s)^T A_\omega \lambda_r - \gamma \left\| \dot{i}_s - \dot{i}_s \right\|^2 - \beta^2 (\dot{i}_s - \dot{i}_s)^T A_\omega \lambda_r. \]
We next analyze the other term is the numerator. Recall that
\[ v_0 \left( | \dot{i}_{sa} - i_{sa} | + | \dot{i}_{sb} - i_{sb} | \right) > -\frac{\gamma}{\beta} \frac{\| \dot{i}_s - i_s \|^2}{| i_{sa} - i_{sa} | + | i_{sb} - i_{sb} |}. \]
Therefore, \( \dot{V} < 0 \) if
\[ \nu > \frac{\beta \left( \dot{i}_s - i_s \right)^T A_\omega \lambda_r}{\| i_{sa} - i_{sa} | + | i_{sb} - i_{sb} |}. \]

The above condition requires careful analysis. Note that for the system in sliding the denominator of the term on the right-hand side of the above condition is 0 and the fraction is not defined. Derdiyok et al. [3] do not discuss this issue in their paper. We analyze the situation as follows. The key is that, in practice, the denominator is small and not identically 0 in sliding and we must be careful that the fraction does not become unbounded as the denominator tends to 0. We analyze the terms in the numerator separately. If \( | \dot{i}_{sa} - i_{sa} | + | \dot{i}_{sb} - i_{sb} | < 1 \), then
\[ \frac{\| i_s - i_s \|^2}{| i_{sa} - i_{sa} | + | i_{sb} - i_{sb} |} < 1. \]
It follows that if \( 0 < | \dot{i}_{sa} - i_{sa} | + | \dot{i}_{sb} - i_{sb} | < 1 \), then
\[ \frac{\| i_s - i_s \|^2}{| i_{sa} - i_{sa} | + | i_{sb} - i_{sb} |} < \frac{\| i_s - i_s \|^2}{| i_{sa} - i_{sa} | + | i_{sb} - i_{sb} |}. \]

We next analyze the other term is the numerator. Recall that
\[ A_\omega \lambda_r = \left[ \begin{array}{c} \nu_1 \\ \nu_2 \end{array} \right]^T. \]
Hence,
\[ \left( \dot{i}_s - i_s \right)^T A_\omega \lambda_r \leq \left( \dot{i}_{sa} - i_{sa} \right) \nu_1 + \left( \dot{i}_{sb} - i_{sb} \right) \nu_2 \leq \max\{ \nu_1, \nu_2 \} \left( \| \dot{i}_{sa} - i_{sa} | + | i_{sb} - i_{sb} | \right). \]
The above inequalities give, for \( 0 < | \dot{i}_{sa} - i_{sa} | + | \dot{i}_{sb} - i_{sb} | < 1 \),
\[ \beta \frac{\left( \dot{i}_s - i_s \right)^T A_\omega \lambda_r}{\| i_{sa} - i_{sa} | + | i_{sb} - i_{sb} |} \leq \beta \max\{ \nu_1, \nu_2 \} \frac{\gamma}{\beta}. \]
We conclude that the fraction is bounded for practical purposes.

When the observation error is in sliding mode along the surface \( \{ s = 0 \} \), we have
\[ \dot{i}_s - i_s = 0 \]
It follows from the above conditions applied to (7) and (8) that in sliding, \( \nu = A_\omega \lambda_r \). Substituting the above into the modeling equation gives
\[ \frac{d}{dt} \lambda_r = -\nu + \eta L_m i_s. \]

We solve the above for \( \lambda_r \) and then using \( \nu = A_\omega \lambda_r \), we obtain
\[ \left[ \begin{array}{c} \nu_1 \\ \nu_2 \end{array} \right] = \left[ \begin{array}{c} \eta \\ -n_{p\omega} \end{array} \right] \left[ \begin{array}{c} \lambda_{ar} \\ \lambda_{br} \end{array} \right] = \left[ \begin{array}{c} \eta \lambda_{ar} + n_{p\omega} \lambda_{br} \\ -n_{p\omega} \lambda_{ar} + \eta \lambda_{br} \end{array} \right] = \left[ \begin{array}{c} \lambda_{ar} \lambda_{br} \\ \lambda_{br} - \lambda_{ar} \end{array} \right] \left[ \begin{array}{c} \eta \\ n_{p\omega} \end{array} \right]. \]

Hence
\[ \left[ \begin{array}{c} \eta \\ n_{p\omega} \end{array} \right] = -\frac{1}{\lambda_{ar}^2 + \lambda_{br}^2} \left[ \begin{array}{c} -\lambda_{ar} \\ -\lambda_{br} \end{array} \right] \left[ \begin{array}{c} \nu_1 \\ \nu_2 \end{array} \right], \]
that is, we have an estimate of the motor time constant, \( \eta \), as well as the rotor speed, \( \omega \).

V. SLIDING MODE OBSERVER OF UTKIN, GULDNER AND SHI

Utkin, Guldner and Shi [4] propose a rotor flux and rotor speed observer where they assume that \( \omega \) is constant when arriving at the proposed observer architecture. To begin with, consider a copy of the induction model subsystem,
\[ \frac{d \hat{\lambda}}{dt} = -A_\omega \hat{\lambda} + \eta L_m \hat{i}_s, \]
\[ \frac{d \hat{i}_s}{dt} = \beta \hat{\omega} \hat{\lambda} - \gamma \hat{i}_s + \frac{1}{\sigma L_s} v_s, \]
where
\[ \hat{\omega} = \omega \text{sign}(s_n), \]
where
\[ s_n = (\dot{i}_s - i_s) \hat{\lambda}_r - (\dot{i}_{sa} - i_{sa}) \hat{\lambda}_r \]
and
\[ \frac{d}{dt} \left[ \begin{array}{c} \hat{\lambda}_r \\ \hat{i}_s \end{array} \right] = -A_\omega \eta L_m \left[ \begin{array}{c} \hat{\lambda}_r \\ \hat{i}_s \end{array} \right] + \left[ \begin{array}{c} 0_{2 \times 2} \\ \frac{1}{\sigma L_s} I_2 \end{array} \right] u_s. \]

Utkin et al. [4, page 225] were not able to provide a proof of the observation error convergence. However, they successfully tested their proposed observer in a laboratory setting.

VI. THE PROPOSED OBSERVER

In this section we use the induction motor model (1) to construct a fifth-order observer. The construction of the proposed observer is inspired by the observer architecture of Thau [7], which is also analyzed in [8], [9]. We add that the Thau observer was generalized by Kou et al. [10] and by
To proceed, we represent the induction motor model (1) in a form suitable for this observer design,

\[
\begin{bmatrix}
\frac{d\theta}{dt} \\
\frac{dL_m}{dt} \\
\frac{di}{dt}
\end{bmatrix} =
\begin{bmatrix}
-\frac{p}{L} & 0 & 0 & 0 & 0 \\
0 & -\eta & 0 & \eta L_m & 0 \\
0 & 0 & -\eta & 0 & \eta L_m
\end{bmatrix}
\begin{bmatrix}
\omega \\
\lambda_{ar} \\
\lambda_{br} \\
i_{as} \\
i_{bs}
\end{bmatrix}
+ \begin{bmatrix}
0 & 0 \\
0 & 0 \\
\frac{1}{\pi L_L} & 0 \\
0 & \frac{1}{\pi L_L}
\end{bmatrix}
\begin{bmatrix}
u_a \\
u_b
\end{bmatrix}
+ \begin{bmatrix}
\mu & 0 \\
0 & -n_p \\
0 & 0 \\
0 & 0
\end{bmatrix}
\begin{bmatrix}
u_a \\
u_b
\end{bmatrix}
= Ax + B_1 u_1 + B_2 u_2(x, \tau_L),
\]

where

\[u_2(x, \tau_L) = \begin{bmatrix}
\lambda_{ar} i_{bs} - \lambda_{br} i_{as} - \frac{1}{\mu J} \tau_L \\
\omega \lambda_{br} \\
\omega \lambda_{ar} \\
i_{as} \\
i_{bs}
\end{bmatrix}.
\]

The output equation is

\[y = \begin{bmatrix}
0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 1
\end{bmatrix}
\begin{bmatrix}
\omega \\
\lambda_{ar} \\
\lambda_{br} \\
i_{as} \\
i_{bs}
\end{bmatrix} = Cx.
\]

Note that the pair \((A, C)\) is detectable but not observable. In fact, the matrix \(A\) has all its eigenvalues in the open left-half complex plane. The designer, however, may decide to shift the observable eigenvalues of \(A\) into prespecified locations, that is, the designer may want find a gain matrix \(L\) such that the eigenvalues of the matrix \((A - LC)\) are as close to prespecified locations in the open left-half complex plane as possible. We assume that the function \(u_2\) representing the nonlinearities of the model satisfies a Lipschitz condition with respect to \(x\) in some neighborhood of the origin, that is, there exists a positive constant \(\kappa\) such that for any \(x\) and \(\hat{x}\) in a neighborhood of the origin,

\[\| u_2(x, \tau_L) - u_2(\hat{x}, \tau_L) \| \leq \kappa \| x - \hat{x} \|,
\]

where the symbol \(\| \cdot \|\) denotes the standard Euclidean norm for vectors and the corresponding induced norm for matrices. The proposed observer has the form

\[\dot{x} = (A - LC)x + B_1 u_1 + L y + B_2 u_2(x, \tau_L)
\]

Let \(e(t) = x(t) - \hat{x}(t)\) be the estimation error. The dynamics of the estimation error are governed by the equation,

\[\dot{e}(t) = (A - LC)e(t) + B_2 (u_2(x, \tau_L) - u_2(\hat{x}, \tau_L)).
\]

Because the matrix \((A - LC)\) is asymptotically stable, there exists, for any symmetric positive definite \(Q\), a symmetric positive definite \(P\) such that

\[(A - LC)^T P + P(A - LC) = -Q.
\]

We next consider the positive definite Lyapunov function candidate, \(V(e) = e^T P e\), for the error system (13). The time derivative of \(V\) evaluated along the solution of (13) is

\[\dot{V}(e) = 2e^T P \dot{e}
\]

\[= 2e^T P(A - LC)e
\]

\[+ 2e^T P B_2 (u_2(x, \tau_L) - u_2(\hat{x}, \tau_L))
\]

\[\leq -e^T Q e
\]

\[+ 2\|e\| \|B_2\| \|\lambda_{max}(P)\| \|e\|^2\]

Taking into account the Lipschitz condition (15), we obtain

\[\dot{V}(e) \leq -\lambda_{min}(Q) \|e\|^2 + 2\kappa \|B_2\| \|\lambda_{max}(P)\| \|e\|^2
\]

\[= - (\lambda_{min}(Q) - 2\kappa \|B_2\| \|\lambda_{max}(P)\|) \|e\|^2.
\]

Hence if

\[\kappa < \frac{\lambda_{min}(Q)}{2 \|B_2\| \|\lambda_{max}(P)\|},
\]

then \(\dot{V}(e) < 0\) and \(e = 0\) is an asymptotically stable state of the error equation (12).

We add here that in our implementation of the proposed observer we have \(L = O\). To evaluate the upper bound on \(\kappa\) that appears in (15), we used \(Q = I_5\), which resulted in \(\kappa < 7.5348 \times 10^{-5}\). Although this upper bound is “very small”, the Lipschitz condition (15) is nevertheless satisfied at \(t = 0\), that is, at the beginning of the first set of our simulations described in Section IX, where we assume the zero initial conditions for the motor and the observer.

In the next section we describe the induction motor drive that we employ in testing our proposed observer.

VII. DESCRIPTION OF THE INDUCTION MOTOR DRIVE EMPLOYED IN SIMULATIONS AND EXPERIMENTS

The performance of the proposed observer is investigated with computer simulations and laboratory experiments using a 4-pole, 460 V, 50 Hp, 60 Hz, delta-connected induction motor whose specification is listed in Table III. The parameters for

\]

The associated inverter with the proposed speed estimator incorporated into the controller architecture is shown in Figure 4. The controller determines, for a given desired torque, the required inverter current, \(i_{abc}^* = [i_{di}^* i_{qi}^* i_{ci}^*]^T\), in the synchronous reference frame and the required slip frequency, \(\omega_s^*\). The controller will be described in greater detail in the following section. Other variables that appear in Figure 4 include the measured a- and b-phase inverter currents, \(i_{ai}\) and \(i_{bi}\), two measured line-to-line inverter voltages, \(u_{abi}\) and \(u_{bci}\), the electrical frequency \(\omega_e\) (which is integrated to determine the position of the synchronous reference frame \(\theta_e\)), the vector of inverter phase current \(i_{abc}^* = [i_{ai}^* i_{bi}^* i_{ci}^*]^T\) and the vector of switch commands \(s_{abc}^* = [s_a^* s_b^* s_c^*]^T\). Setting \(s_a^*\) high indicates the upper transistor of x-phase should be turned on (and the lower transistor off), where ‘x’ may be ‘a’, ‘b’, or ‘c’. The vector of stator voltages in the stationary frame, \(u_s\), is obtained from the measured line-to-line inverter voltages, \(u_{abi}\) and \(u_{bci}\), employing first the \(K_s^{-1}\) transformation followed by the wye-delta conversion, where

\[
K_s^{-1} = \begin{bmatrix}
\sin(\theta_e) & \cos(\theta_e) & 1 \\
\sin(\theta_e - \frac{2\pi}{3}) & \cos(\theta_e - \frac{2\pi}{3}) & 1 \\
\sin(\theta_e + \frac{2\pi}{3}) & \cos(\theta_e + \frac{2\pi}{3}) & 1 \\
\end{bmatrix}
\]

A delta modulator is used to generate the switching commands, \(s_{abc}\), for switching devices of the inverter \(T_1, \ldots, T_6\). Every \(T_{sw}\) seconds, the modulator calculates the phase current error between \(i_{x1}\) from the SCR and \(i_{x1}\) as

\[
e_{x1} = i_{x1}^* - \gamma_{x1},
\]

where ‘x’ may be ‘a’, ‘b’, or ‘c’. Based on the sign of error in each phase in (16), switching command \(s_x^*\) is determined by

\[
s_x^* = \begin{cases}
1 & \text{if } e_{x1} > 0 \\
0 & \text{if } e_{x1} < 0.
\end{cases}
\]

The switching of the three phases is evenly staggered in time. For our study, \(T_{sw}\) is 100 \(\mu s\).

VIII. DESCRIPTION OF THE CONTROL STRATEGY

In our simulations and lab experiments, we used an alternative q-d induction machine model (AQDM) using the maximum torque per amp (MTPA) control strategy recently proposed by Kwon and Sudhoff [14], [15]. We use the MTPA control strategy to validate the performance of the proposed speed estimator by using the estimated speed generated by the proposed speed estimator instead of the speed obtained from the mechanical speed sensor. In this section, we briefly review this AQMD based MTPA control strategy.

This control strategy was designed such that even induction machines that are driven at light or moderate loads for significant portions of their service life would operate with high efficiency. It is simple in structure and accounts for the effects of magnetizing and leakage saturation. The objective of this control strategy is to produce a desired torque with the minimum current that is favorable in terms of inverter losses and nearly optimal in terms of efficiency [16, Chapter 14]. In this control strategy, the root-mean-square magnitude of the stator current \(I_s\) and the slip frequency \(\omega_s\) are expressed as functions of the desired torque, \(T_e^*\). Kwon and Sudhoff [14], [15] has experimentally demonstrated that for the entire torque range, the proposed control strategy can find a slip frequency at which the produced torque is optimal for a given stator current (the maximum torque per amp condition) and is close to the desired torque. The steady-state equivalent circuit corresponding to the AQDM that was proposed in [14], [15]
The parameters in this equivalent circuit are:

\[
L_{ls} = l_{s1} \text{ (which is a constant)}
\]

\[
L_{lr} (\lambda_m) = l_{r1} + \frac{l_{r2}}{1 + l_{r3} \lambda_m l_{r4}}
\]

\[
\Gamma_m (\lambda_m) = m_1 - m_2 \lambda_m + e^{m_3 (\lambda_m - m_4)} + e^{m_5 (\lambda_m - m_6)}
\]

\[
Y_r (s) = \frac{y_{a1}}{y_{r1} s + 1} + \frac{y_{a2}}{y_{r2} s + 1} + \frac{y_{a3}}{y_{r3} s + 1},
\]

where \( s \) denotes the differentiation operator in the Laplace domain. The AQDM parameters of the test induction motor were obtained using the method proposed in [14], [17]. The resultant motor parameters of the AQDM for this test motor are listed in Table V. Using the AQDM parameters given in Table V, an MTPA control strategy can now be derived. First note that the electromagnetic torque in the synchronous

</table>
reference frame may be written as

\[ T_e = \frac{3}{2} n_p \left( \lambda_{qm}^e i_{ds}^e - \lambda_{dm}^e i_{qs}^e \right). \]  

(18)

It is convenient to express (18) in terms of the slip frequency and the rms magnitude of the applied stator current. The relationship between the d-axis stator current in phasor representation and the d- and q-axis currents in the synchronous reference frame is

\[ \sqrt{2} i_{ds} = i_{ds}^e - j i_{qs}^e. \]  

(19)

Without loss of generality, we select the phase reference such that all the current is in the d-axis and reduce (19) to

\[ \sqrt{2} I_s = i_{ds}^e, \]  

(20)

where \( I_s \) is the magnitude of \( i_{ds} \) which has only one component. Similarly, the relationship of magnetizing flux linkages may be expressed as

\[ \sqrt{2} \lambda_{dm} = \lambda_{dm}^e - j \lambda_{qm}^e. \]  

(21)

After algebraic manipulations of (18) and (21), we rewrite the electromagnetic torque in terms of the stator current and magnetizing flux linkage phasors as

\[ T_e = 3 n_p \Im \left( \lambda_{dm} I_s \right), \]  

(22)

where \( \Im (-) \) denotes the operation of taking the imaginary part of the expression in the parentheses and the bar indicates the operation of complex conjugation. Using the AQDM steady-state equivalent circuit of Figure 6, we express \( \lambda_{dm} \) as

\[ \lambda_{dm} (\omega_s, I_s) = \frac{Z_{ag} (\lambda_m, \omega_s)}{j \omega_c} I_s, \]  

(23)

where

\[ Z_{ag} (\lambda_m, \omega_s) = -j \Gamma_m (\lambda_m) + \frac{\omega}{j \omega_s k_s (\lambda_m) + \frac{\omega}{\tau_s \omega_s}} \]  

(24)

and the subscript ‘ag’ in \( Z_{ag} \) indicates the impedance looking into the air-gap of the induction machine. The electromagnetic torque can now be expressed in terms of only \( \omega_s \) and \( I_s \). Substituting (23) into (22) yields

\[ T_e (\omega_s, I_s) = 3 n_p \Im \left( \frac{Z_{ag} (\lambda_m, \omega_s)}{j \omega_c} I_s \right). \]  

(25)

Note that the \( \omega_c \) appearing in \( Z_{ag} \) in (24) cancels out the \( \omega_c \) in the denominator of (25), and so \( T_e (\omega_s, I_s) \) is independent of \( \omega_c \). Next, we note that \( \lambda_m = \lambda_m (\omega_s, I_s) \) that appears in (25) satisfies the condition \( \lambda_m = \sqrt{2} |\lambda_{dm}| \) and can be calculated by solving the nonlinear algebraic equation

\[ |\omega_c \lambda_m| = \sqrt{2} |I_s Z_{ag} (\lambda_m, \omega_s)| \]  

(26)

using, for example, the Newton-Raphson method for a given \( \omega_s \) and \( I_s \). We can now present a procedure for constructing an MTPA control strategy using (25). First, a set of stator current commands for \( I_s \) is be selected from nearly 0 A to somewhat over the rated current. The \( k \)-th point is denoted \( I_{s,k} \). The optimum slip frequency for each current is identified by numerically maximizing (25) with \( I_s = I_{s,k} \). The resulting value of the slip frequency is denoted \( \omega_{s,k} \) and the corresponding value of the torque is denoted \( T_{e,k} \). These data points are shown in Figure 7. Next, these data points are used to construct a stator current and slip frequency control law. The data points \{\( I_{s,k}, T_{e,k} \)\} are used to formulate a stator current control law of the form

\[ I_{s}^* = a_1 T_{e}^* + a_2 T_{e}^{*b_1} + a_3 T_{e}^{*b_2}, \]  

(27)

where \( a_1, a_2, a_3, b_1, \) and \( b_2 \) are selected by maximizing the objective fitness function defined by

\[ f_{MTPA} = \frac{1}{\epsilon + \sqrt{\frac{1}{N_K} \sum_{k=1}^{N_K} |I_{s,k} - I_{s,k}^*|}}, \]  

(28)

Fig. 7. MTPA control law based on AQDM.
where $\epsilon$ is a small number ($10^{-3}$) that is added to the denominator in order to prevent singularities in the unlikely event of a perfect fit, $N_K$ is the size of a set of stator current commands, and $I_{s,k}^*$ is given by (27) with $T_e^* = T_{e,k}$.

Similarly, the data points $\{\omega_{s,k}, T_{e,k}\}$ are used to formulate a slip frequency control law of the form

$$\omega_s = c_0 + c_1 T_e^* + c_2 T_e^{*2} + c_3 T_e^{*3} + c_4 T_e^{*4},$$

(29)

where $c_0, c_1, c_2, c_3,$ and $c_4$ are also chosen by maximizing (28) with $I_s$ replaced with $\omega_s$. We obtain $\omega_{s,k}^*$ from (29) with $T_e^* = T_{e,k}$. Together, (27) and (29) form the MTPA control strategy. Applying the above procedure to the test induction motor whose AQDM parameters are given in Table V, the formulas given by (27) and (29) become

$$I_s^*(T_e^*) = 0.1097 T_e^* - 17.07 T_e^{*0.0177} + 18.5 T_e^{*0.0799}$$

(30)

and

$$\omega_s^*(T_e^*) = 1.4 - 2.4 \times 10^{-3} T_e^* + 176 \times 10^{-6} T_e^{*2} - 933 \times 10^{-9} T_e^{*3} + 1.74 \times 10^{-9} T_e^{*4}.$$ (31)

The final analytically obtained values of the resulting MTPA control law based on the AQDM are also depicted in Figure 7.

IX. SIMULATION STUDIES

We performed computer simulations of the induction motor drive using the Advanced Continuous Simulation Language (ACSL) [18]. We note that the variables related to the MTPA control strategy were transformed into the synchronous reference frame while the variables used in the proposed estimator were transformed into the stationary reference frame. The first simulation study focused on the performance of the proposed speed estimator in an application where the characteristic of the load torque is known to have a form where the load torque is proportional to the mechanical rotor speed. The desired torque to the MTPA control strategy is set at 150 Nm and the estimated load torque employed by the proposed observer is proportional to the estimated rotor speed. Both initial conditions of the plant and the proposed estimator are set to zero. The results of this study are summarized in Figure 8. As can be seen in the figure, the proposed estimator predicts the rotor speed with good accuracy during the transient period as well as in the steady state period. Approximately 10% speed error is observed one second into the simulation, which then decreases. There is also some deviation in the stator current. This needs to be further investigated in future research.

The objective of the second study was the performance of the proposed estimator in an application where the characteristic of the load torque is unknown. We assumed that the transient response of the induction motor was short enough so that the load torque was equal to the the estimated electromagnetic torque. This enabled us to make use of the same equation as the estimated electromagnetic torque using the measured stator currents. Note that the measured stator currents are present in $\tau_L$. In the experiment the test induction motor was driven to 900 rpm by the dynamometer and controlled in the torque mode with the desired torque of 150 Nm by the MTPA control strategy. The results of this simulation study are collected Figure 9, which shows that even though there are big deviations in the transient periods due to different initial conditions, the proposed estimator starts to track the actual speed closely in under 2 seconds.

X. EXPERIMENTAL STUDIES

In order to see if the results of computer simulations, described in the previous section, would predict the functioning of the proposed observer in real applications, its performance was investigated in a laboratory experiment, where the estimated load torque is unknown. The estimated load torque used by the proposed observer was obtained using the electromagnetic torque equation employing the measured stator currents. Therein, the test induction motor was driven
to 900 rpm with the torque command of 150 Nm using the MTPA control strategy. The results are shown in Figure 10. The experiment shows that the measured and estimated speeds are in good agreement during the steady-state period. The maximum speed estimation error is around 2.5%. We conclude that the proposed observer works well using stator voltages and measured stator currents in the estimated load torque in the steady state, that is, when the electromagnetic and load torques are equal. The second study was performed to investigate the tracking capability of the proposed estimator during the transient period with the same conditions as in the first experiment except that the rotor speed was varied arbitrarily in the range of 500 rpm to 900 rpm. As can be seen in Figure 11, the estimated speed follows the measured speed very closely during the steady state response, and even during the transient response. However, there are some deviations of the estimated stator currents from the measured currents. Further study is required to improve the proposed observer architecture in order to reduce the estimation error. Next, the application of the proposed estimator to speed sensorless induction machine drive was considered. We incorporated the proposed estimator into the MTPA control strategy based induction machine drive as shown in Figure 4, where we replaced the actual rotor speed, \( \omega \), by its estimated value, \( \hat{\omega} \), produced by the proposed estimator. This laboratory experiment was conducted with the test induction motor driven at a speed of 900 rpm at a desired torque of 150 Nm. The electromagnetic torque measured at the estimated optimal slip frequency command \( \omega_s^* \) defined in (31) was compared with the two sets of torque measurements taken at 0.9 and 1.1 times the slip frequency command \( \omega_s^* \) in (31). These results are compared with the results of the MTPA control strategy based induction machine drive that uses the measured rotor speed and are shown in Figure 12. In both cases, the torque measured at the estimated optimal slip frequency command \( \omega_s^* \) in (31) is larger than the torque produced at any other slip frequency indicating that the estimated speed is accurate enough to substitute for the mechanical rotor speed sensor in this application. Note that the performance of the MTPA control strategy with the proposed estimator incorporated into the controller turns out to be poor because the speed estimation error is relatively large compared with the slip frequency command despite that the error is less than 1% at very light loads. Further studies on improving the observer performance at light loads is desired.

**XI. CONCLUSIONS**

In this paper, we investigated the use of observers in the sensorless control of induction motor drives. The three recently proposed rotor flux and speed observers [1], [3], [4] employed the fourth-order induction motor model assuming constant rotor speed and utilizing the measured stator currents. These observers perform well in the steady state or when the speed does not change aggressively. In the papers mentioned above, the performance of the proposed observers when the rotor
speed changes aggressively was not investigated. This aspect motivated us to employ the fifth-order induction motor model to propose an alternative rotor flux and speed observer. Simulation and laboratory experimental studies demonstrate that the proposed rotor flux and speed observer could do an excellent job in predicting the speed during the transient and steady state periods, even when applied in the sensorless control of the induction motor drives. However, further analysis should be performed to investigate the deviations of the estimated stator current from measured current when rotor speed changes aggressively, for example, from 500 rpm to 900 rpm.
